Book version: B1.0—March 22, 2017

Phoenix is a great web framework. It's fast, really fast. Its components are familiar and easy to work with. Phoenix is lightweight, modular, and explicit. There's almost no hidden magic. That's a big boost for maintainability.

Frameworks are nearly ubiquitous in web development today. For either the front end or backend, almost everyone uses some form of framework to build web applications.

There's good reason for this. Frameworks get us up and running quickly. They remove the need to re-implement common tasks for every project—routing, handling request parameters, and the like. Frameworks let us focus on our individual application's behavior instead of repetitive tasks.

The slippery slope is that frameworks make it all too easy to tangle the framework components and the application together in ways that really hurt us.

OTP Applications let us get around this in an elegant way. Phoenix itself is an OTP Application. The game engine we built in part one of the book is also an OTP Application.

Our task in part two of this book is to create a web interface with Phoenix for our game. We're going to use the Phoenix and game engine OTP Applications as building blocks to create a third Application that will keep the Phoenix interface separate from the game in a way that will make our job trivially easy.

## Frameworks

Framework components represent what is common to all web applications. That's why the framework creators extracted them out into the framework. This is a great boon to developers because we don't need to solve the same problems over and over again. Things like routing requests to the right handler functions, getting the request parameters, handling response templates, setting cookies, the framework takes care of all that for us. The framework components make it easy interact with the business logic over the web. They make up the web interface for the application.

The business logic is unique to each application. This is the part that we can't extract into a common framework. It's what makes our application do interesting things, and gives it value. It's the most important part to us, because the success or failure of our application depends on how well this works.

But there's a serious, hidden-in-plain-sight problem here. We're so habituated to it that we hardly even notice.

## Coupling

The way we normally build business logic with a framework is completely backwards. We create application behavior by adding more pieces of the framework—routes, controllers, models, and views. Each new model or controller we add contains a bit more logic. This mixes our business domain with the domain of the framework, and it couples the two inextricably and forever.

Why is that a big deal? We can't easily reuse the business logic with another interface. We can't test our business logic in isolation, outside the context of the framework code.

Let's say we wanted both a web interface and a Nerves device version of Islands. If we didn't have a separate OTP Application for Islands, we would need to completely re-implement the business logic for each interface.

Whenever we need to send an HTTP request to test a business rule, an alarm should go off at our workstation. Business rules should be completely separate from how we handle HTTP requests. Yet this is how we've been trained to test web applications.

This is why upgrading a framework to a new major version can sometimes be so painful. It's also why switching frameworks entirely seems like a herculean task. The way we normally work with frameworks makes this pain almost inevitable.

## Phoenix is not Your Application

It's important to think about how we got into this situation, so we know how to get out of it.

The way we talk about web applications gets us in trouble right away. We say, "I'm building a Rails app." or an Ember app or a Phoenix app or an Elm app.

But that's not true. What we're really doing is building a chat app, or a banking app, or a game called Islands, with a Phoenix interface or an Ember interface or an Elm interface.

The problem is deeper than that though. There are a number of ways to look at it, but this resonates most with me. ORMs lead us directly into this coupling of business logic and framework components.

ActiveRecord models in Rails offer the clearest example of this, but the same idea applies across many frameworks. Let's say we are working in a domain

in which one of the entities is a bicycle. We could begin modeling this with a plain Ruby class.

```
class Bicycle
  # We define bicycle-specific properties and behavior here.
end
```

We might define bicycle properties here like wheels, handlebars, pedals, and brakes. We could also define behaviors like pedaling, steering, and braking.

Rails tends to push us toward putting domain models, like our Bicycle class, in a database. ActiveRecord makes this very easy. We just have a model class inherit from ActiveRecord::Base.

```
class Bicycle < ActiveRecord::Base
  # Suddenly, bicycle behavior is mixed with database behavior.
end
```

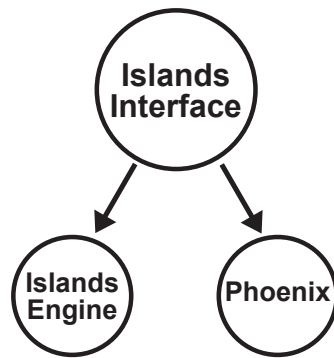

With this small change, everything is different. Our Bicycle class suddenly knows a lot more than just bicycle things. It knows how to connect to a database, read from and write to a table, validate data, perform transactions, generate queries, and a whole host of other things.

Our domain, in which a bicycle is just a bicycle, is suddenly entwined with the Rails domain, in which a Bicycle model is an interface to a database table. Once this happens, the two domains become glued together, and can't be separated without a rewrite.

## Decoupling

That's not going to happen here. We already have our game logic separated out. Now we're going to layer on the web interface. The two will live happily side by side, and they won't be tightly coupled.

We built the core logic of the game as an OTP Application. That means we can bring it into any other OTP Application as a dependency, and all of its functionality will be available to us. Phoenix happens to be an OTP Application, which makes this job a snap. This one idea, this way of managing dependencies and building applications is quietly revolutionary. It's going to make the rest of our work with Phoenix seem trivial.

Of course, Erlang developers have been working in this quietly revolutionary way for a couple of decades now.

All our core logic needs is a web interface, and we'll use Phoenix to build one. Phoenix has all of the MVC components you're used to for those times when HTTP's request/response cycle fits best. It's also got a realtime, persistent connection layer called Channels built right in.

This is where all our hard work up to now is going to really pay off. From here, we'll be able to generate a fresh Phoenix application and bring our whole game in as a dependency. As we build out the interface, we won't be mixing in any application logic. We'll just call into the public interface of the game server that we've already built. There won't be any entanglement between the game and the interface.

OTP Applications are what allow us to build these separate, self-contained components. They're what allow us to compose them back together into larger applications as well. We'll explore them next.

## OTP Applications

Despite the name, OTP Applications are not what we normally think of as software applications. They are reusable units of code that are bigger than modules. In fact, they most often contain multiple modules. They're similar in scale to libraries in other ecosystems. While they can function as libraries, they can also be so much more.

Applications can act as true building blocks for our programs, a means of putting together integral pieces of business logic to build a larger whole. Working with larger building blocks like these makes us really productive.

Applications can also stand on their own as what we traditionally think of as an application. The IslandsEngine application we developed in the first part of the book is one example. It is a fully functioning game just as it is, albeit with a pretty unfriendly user interface. As complete as it is, we can still use it as a building block for something larger, as we'll soon see.

`:application` is a specific OTP Behaviour written in Erlang, just like `:gen_server` and `:gen_statem`. There is a module in OTP which defines `:application` specific functions as well as a list of callbacks we need to implement. Elixir provides a wrapper module around the pure Erlang one called `Application`. We'll be using the Elixir wrapper most often in this chapter.

The `Application` Behaviour lets us do three things. It lets us define and name Applications. It facilitates dependency management among Applications. We can define hierarchies of `Application` dependencies, and the Behaviour will make sure they work correctly. The Behaviour also facilitates cleanly starting and stopping individual applications in a running BEAM.

“Cleanly” here means two things. It makes sure to start any dependent Applications before it starts itself. It also keeps track of any processes the `Application` spawns during startup or while it's running, and makes sure to stop them when the `Application` stops.

Now that we've got an idea of the significance of OTP Applications, let's dig a little deeper and see how they work.

## Understanding OTP Applications

The good news is that we've been working with an OTP Application all along. At the beginning of the book, when we generated the brand-new IslandsEngine project, Mix automatically created it as an OTP Application. We didn't need to look deeply at the `Application` Behaviour then because IslandsEngine stood on its own for our purposes.

Now, though, we need to use it as a dependency, as a building block to create a larger project—the web interface we're going to build in this chapter. Understanding `Application` dependencies will clarify our work on this project, and any other Elixir projects we work on.

We already have examples of the `Application` Behaviour related files in IslandsEngine. We'll use them to understand dependency management as

well as starting and stopping individual applications inside the BEAM. We'll see first hand the independence of OTP Applications that let's us solve the coupling problem so prevalent in web applications.

There are three parts to the implementation of an OTP Application, and Mix has a hand in all of them.

When we generate a project with `mix new` we get a file named `mix.exs` at the root of our project. `mix.exs` defines key aspects of the application, everything from its name and version number to a list of applications it depends on to build the project.

Mix also generates a Behaviour callback module in the `/lib` directory named after our project. In the case of our game engine, it generated `/lib/islands_engine.ex`. If we supply the `--sup` flag to `mix new`, the callback module will contain the `start/2` callback function necessary to start the top level supervisor for the application. Without `--sup`, the file will be there, but it will be empty.

Once we compile the project, `mix` will generate an application resource file, written in Erlang, that the BEAM will use to work with our application.

Let's take a look at these files now starting with `mix.exs`.

## Managing Dependencies

Any project's `mix.exs` file has two main functions—defining a project's metadata and managing its dependencies. Of the two, dependency management is by far the most common thing developers do, and it's the most important for our purposes as well.

Three functions defined in `mix.exs` do all the work for us. The `project/0` function returns a keyword list of metadata about the application.

```
def project do
  [app: :islands_engine,
   version: "0.1.0",
   elixir: "~> 1.0",
   build_embedded: Mix.env == :prod,
   start_permanent: Mix.env == :prod,
   deps: deps()]
end
```

The app name, version number and Elixir version are pretty self-explanatory. `build_embedded`: makes sure that compilation artifacts end up in the `_build` directory. In this case, that would be true for the production environment. `start_permanent`: starts the system in such a way that the BEAM will crash if the

top level supervisor crashes. This will be true for the production environment as well.

The `deps` key holds a list of build-time dependencies this application depends on. The value here is the return value of the `deps/0` function, also defined in `mix.exs`.

```
defp deps do
  []
end
```

`IslandsEngine` has no dependencies, so the return value here is an empty list. When we generate a new Phoenix application in the next section, we'll see an example with a number of dependencies.

There are actually two types of dependencies for OTP Applications, those that matter for runtime, and those that come into play for build/compile time. Mix uses the dependencies listed in the `deps/0` function to build the project. Any application in this list can have its own dependencies. This is how we can compose a larger tree of dependencies, just as we saw with supervision trees in [Chapter 5, Process Supervision For Recovery, on page ?](#).

The last function in `mix.exs` is `application/0`. It returns a keyword list of data related to starting the application. The value of the `:extra_applications` key is a list of application names which are the runtime dependencies. Mix will make sure these are running before it starts `:islands_engine`. `:mod` holds a tuple for the module name of the callback module as well as a list of options that the `start/2` function in that module might need.

```
def application do
  [extra_applications: [:logger],
   mod: {IslandsEngine, []}]
end
```

`IslandsEngine` only depends on the `:logger` application at runtime. This dependency is a default for all OTP Applications Mix generates. Elixir itself supplies this, so we don't need to list it in the `deps/0` function.

The reason that there are two different places to define dependencies is that it's possible to need a dependency for compilation, but not need it to be running inside the BEAM, and visa versa.

If our application doesn't have a supervision tree, for example if we omitted the `--sup` flag when we generated the project, we can omit the `mod` key completely.

```
def application do
```

```

    [extra_applications: [:logger]]
  end

```

You might be thinking that this seems a little redundant. Shouldn't Mix be able to infer the application list from the deps list as long as we give it some clues? As of Mix 1.4, it can.

If the runtime dependencies are the same as the compile time ones, we can omit the `:extra_applications` key in `application/0`.

```

def application do
  [mod: {IslandsEngine, []}]
end

```

If there are runtime dependencies not listed in the `deps/0` function, `:logger` for instance, we can handle that with the `:extra_applications` key.

```

def application do
  [extra_applications: [:logger],
   mod: {IslandsEngine, []}]
end

```

And if we have compile time dependencies that we don't need to start when we start our application, we can mark them as `runtime: false` in the `deps/0` function.

```

defp deps do
  [ {:some_new_dep, "> 0.0.0", runtime: false} ]
end

```

That brings us to the end of dependency management in `mix.exs`. Once we have dependencies defined, we need to be able to start them inside the BEAM. That's where we're headed next.
