## Restructuring WebRTC Callbacks with Closures

So far, rewriting the peer-to-peer code to work on multipeer calls has been pretty straightforward. Well, fairly straightforward. Fine—*straightforwardish*, the way an alien abduction is straightforward. However you want to spin it, your work towards a multipeer WebRTC app has required shifting some logic around on the signaling callbacks and introducing a new `id` variable to a number of functions.

By contrast, the revisions you'll make to your WebRTC callbacks require rethinking your approach to callbacks entirely, especially how the callbacks themselves are registered.

Let's step back and think about peer IDs for a moment: each of your WebRTC callbacks needs to be associated with a specific peer ID's `RTCPeerConnection` instance. Accessing IDs wasn't a problem with signaling callbacks: peer IDs are included in all data returned by the signaling channel's events. But neither the `RTCPeerConnection` object nor the data its events return have any access to peer IDs. And that's a problem, because unique peer IDs are central to the way we're architecting multipeer, mesh-networked calls.

Providing the correct ID value to each WebRTC callback that needs it is a trickier proposition than it might sound. But it's not impossible. Let's start big-picture and open up the `registerRtcCallbacks()` function, modify it to take an `id` argument that will be passed into the function from within `establishCallFeatures()`, and prepare each of its event assignments so that we're passing in the ID for a specific peer. Remember that `establishCallFeatures()` is executed for each peer on a call, thanks to the logic you wrote just a moment ago in [Fleshing Out the Skeletal Signaling Callbacks, on page ?](#):

```
demos/multipeer/js/main.js
```

```
/**
 * WebRTC Functions and Callbacks
 */
function registerRtcCallbacks(id) {
  const peer = $peers.get(id);
  peer.connection
  ➤ .onconnectionstatechange = handleRtcConnectionStateChange(id);
  peer.connection
  ➤ .onnegotiationneeded = handleRtcConnectionNegotiation(id);
  peer.connection
  ➤ .onicecandidate = handleRtcIceCandidate(id);
  peer.connection
  ➤ .ontrack = handleRtcPeerTrack(id);
}
```

Just like you did with `addStreamingMedia()`, you're setting up a function-scoped peer variable inside `registerRtcCallbacks()`. But something probably looks off about those rewritten callback assignments. In [Writing Named Functions as Callbacks, on page ?](#), you read about how it is a very big deal to make sure that callback functions are passed in or assigned by reference, without parentheses. But here, not only are you calling functions with parentheses, but you're even passing each of them an id value. That will blow up all of the peer-to-peer WebRTC callbacks you wrote previously, which destructured data returned by the WebRTC events that triggered them.

That's a big problem: the rules have not changed on callback assignments. The callbacks assigned to WebRTC events must still reference functions to be executed when each associated event fires—now with the added complexity of firing on a specific `peer.connection` instance, too.

What we need to do, then, is restructure all of the peer-to-peer WebRTC callback functions to create closures.<sup>10</sup> In other words, each of the existing WebRTC callbacks must be rewritten so as to return a function when executed. When a WebRTC event fires, it will execute the returned function, which must be capable of receiving and acting on the WebRTC event's data.

Let's try expressing those abstract ideas as real code. Right below the `registerRtcCallbacks()` function definition, find the `handleRtcPeerTrack()` callback. Think back to how you wrote that function to display the media streaming in from a single remote peer:

```
// main.js, peer-to-peer logic
function handleRtcPeerTrack({ track }) {
  console.log(`Handle incoming ${track.kind} track...`)
  $peer.mediaTracks[track.kind] = track;
  $peer.mediaStream.addTrack(track);
  displayStream($peer.mediaStream, '#peer');
}
```

We must do two things to rewrite that callback to create a closure: first, we'll grab the ID argument that's being passed into `handleRtcPeerTrack()` from within `registerRtcCallbacks()`. And then we'll change the body of `handleRtcPeerTrack()` to return a function—an anonymous but otherwise identical version of the original callback that you wrote—which will be called when the track event actually fires the peer connection for that ID value:

```
demos/multipeer/js/main.js
function handleRtcPeerTrack(id) {
  ➤ return function({ track }) {
```

10. <https://developer.mozilla.org/en-US/docs/Web/JavaScript/Closures>

```

➤   const peer = $peers.get(id);
    console.log(`Handle incoming ${track.kind} track from peer ID: ${id}`);
    peer.mediaTracks[track.kind] = track;
    peer.mediaStream.addTrack(track);
    displayStream(peer.mediaStream, id);
➤   };
  }
}

```

If you've not worked with closures before, the idea behind them is that the returned function is capable of holding onto the values of any variables, like `id`, from the scope of the outer function: in this case, `handleRtcPeerTrack()`. The anonymous function returned by `handleRtcPeerTrack()` is what's actually assigned to the `peer.connection.ontrack` event property. Note that the anonymous function is still neatly destructuring the `track` from the event, too.

In slightly more concrete terms: the new function returned by `handleRtcPeerTrack()` must fire on the `track` event for a specific remote peer. Preserving the reference to that peer's ID is made possible by the closure. The ID value makes it possible to continue to preserve the tracks and stream on the peer's record in the `$peers` map. The peer's ID itself must also be passed into the `displayStream()` function [you wrote back on page ?](#).

In slightly more nerdy terms: the inner anonymous function has access to the outer function's lexical scope, including the `id` value, at the moment the anonymous function is defined. That's the magic of closures in JavaScript: we can preserve custom values for use inside a callback function without messing with the set structure of arguments passed into the callback at runtime.

Enough nerding out. Let's keep going. If you're still feeling uncertain about closures, that's okay. Their behavior should become clearer as you write a few more. Find the "Reusable WebRTC Functions and Callbacks" area of your `main.js` file and rewrite those three callbacks to use closures, too. You can go in order, and prove to yourself what a champ you are by starting with `handleRtcConnectionNegotiation()`, which also involves the signaling channel:

```

demos/multipeer/js/main.js
/**
 * Reusable WebRTC Functions and Callbacks
 */
function handleRtcConnectionNegotiation(id) {
  return async function() {
    const peer = $peers.get(id);
    const selfState = peer.selfStates;
    selfState.isMakingOffer = true;
    await peer.connection.setLocalDescription();
    sc.emit('signal',

```

```

    { recipient: id, sender: $self.id,
      signal: { description: peer.connection.localDescription } });
    selfState.isMakingOffer = false;
  };
}

```

Here you're making use of the self states associated with a specific peer ID, which for the sake of brevity gets its own variable assignment (selfState) for use in the connection-negotiation callback's logic.

Beyond that adjustment in how you reference self states, the most significant change to handleRtcConnectionNegotiation() is on its call to the sc.emit() method. In the peer-to-peer code, that call looked like this:

```

// main.js
// snip, snip...
sc.emit('signal',
  { description: $peer.connection.localDescription });
// snip, snip...

```

But in a multipeer setup, it's necessary to include the recipient and sender values for properly routing signals over the signaling channel whenever you call sc.emit()—just like you did for the handleScSignal() callback in [Correcting Variable References, on page ?](#). The routing values are made accessible from the returned anonymous callback function, care of the closure around id.

See? You are indeed a closure champ. You can make quick work of rewriting the other two reusable WebRTC callbacks as closures, too. They're less complicated by comparison.

The ICE-candidate callback needs to reference an id for routing each candidate to the correct peer:

```

demos/multipeer/js/main.js
function handleRtcIceCandidate(id) {
  return function({ candidate }) {
    sc.emit('signal', { recipient: id, sender: $self.id,
      signal: { candidate } });
  };
}

```

We can also write a diagnostic closure on the connection state-change callback. It doesn't make sense to add a class to the body in a multipeer setting (all of the changes from multiple peers' connection states would just clobber each other), but what we can do instead is reference an element and add the connection state there, assuming the element exists. Because this is meant to be reusable code, let's opt for a generic peerElement, so that it reads sensibly even when there aren't video elements as part of the interface—something

we'll see in *the (as yet) unwritten Chapter 8, Building Peer-to-Peer Interfaces*. The `connectionstate` event will first fire immediately, likely before the peer element has been added to the self side of the call. So we check for the element's existence before doing anything with it:

`demos/multipeer/js/main.js`

```
function handleRtcConnectionStateChange(id) {
  return function() {
    const peer = $peers.get(id);
    > const connectionState = peer.connection.connectionState;
    > // Assume *some* element will take a unique peer ID
    > const peerElement = document.querySelector(`#peer-${id}`);
    > if (peerElement) {
    >   peerElement.dataset.connectionState = connectionState;
    > }
    console.log(`Connection state '${connectionState}' for Peer ID: ${id}`);
  };
}
```

When the element exists, the function preserves the connection state in a `data-connection-state` attribute, care of the dataset property.<sup>11</sup> The camelCased `dataset.connectionState` property will automatically convert to a dash-styled `data-connection-state` attribute in the DOM. The latest state will always replace any older state on the `data-connection-state` attribute.

And with that, all of your WebRTC callbacks are properly using closures to return id-backed anonymous functions.
